Software Security Memory corruption

public enemy number 1

Erik Poll

Digital Security

Radboud University Nijmegen

Overview (next 2 weeks)

- 1. How do memory corruption flaws work?
- 2. What can be the impact?
- 3. How can we spot such problems in C(++) code?

Next weeks: tool-support for this

- static analysis aka SAST: PREfast indvidual project
- testing aka DAST: Fuzzing group project
- 4. What can 'the platform' do about it?
 ie. the compiler, system libraries, hardware, OS, ...
- 5. What can the programmer do about it?

Reading material

- SoK article: 'Eternal War in Memory' S&P 2013
 - Excl. Section VII.
 - This article is quite dense. You are not expected to be able to reproduce or remember all the discussion here. It's good enough if you can follow the article, with a steady supply of coffee while googling if the terminology is not clear.
- Chapter 3.1 & 3.2 in lecture notes on memory-safety
 We'll revisit safe programming languages incl. other safety
 features and rest of Chapter 3 in later lecture

Essence of the problem

Suppose in a C program you have an array of length 4 char buffer[4];

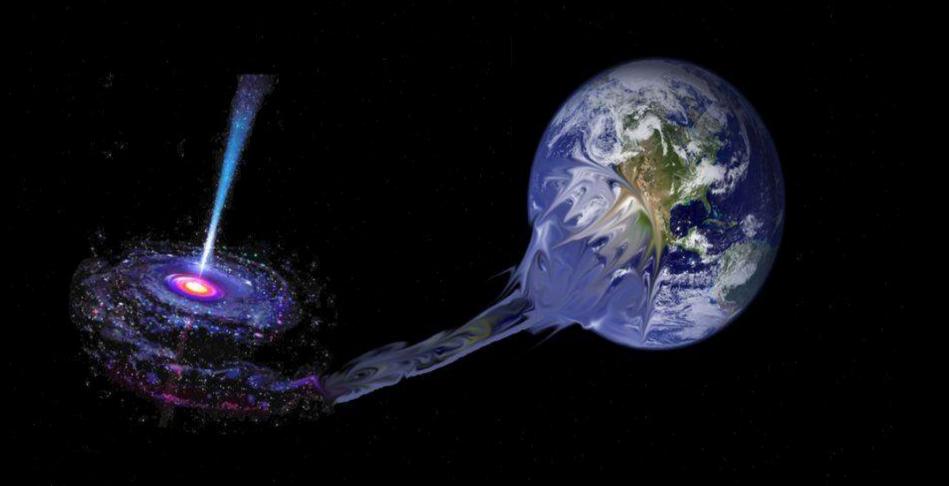

What happens if the statement below is executed?

buffer[4] = 'a';

This is defined to be undefined

ANYTHING can happen

Suppose in a C program you have an array of length 4

```
char buffer[4];
```

What happens if the statement below is executed?

```
buffer[4] = 'a';
```

If the attacker can control the value 'a' then anything that the attacker wants may happen

- If you are lucky, you only get a SEGMENTATION FAULT
 - and you'll know that something went wrong
- If you are unlucky, there is remote code execution (RCE)
 - and you won't know

Suppose in a C program you have an array of length 4

```
char buffer[4];
```

What happens if the statement below is executed?

```
buffer[4] = 'a';
```

A compiler could remove the statement above, ie. do *nothing*

- This would be correct compilation by the C standard because anything includes nothing
- This may be unexpected, but compilers actually do this (as part of optimalisations) and this has caused security problems; examples later & in the lecture notes

Solution to this problem

- Check array bounds at runtime
 - Algol 60 proposed this back in 1960!
- Unfortunately, C and C++ have not adopted this solution.
 - Why?
 - For EFFICIENCY

Regrettably, people often choose performance over security

- As a result, buffer overflows have been the no 1 security problem in software ever since.
- Fortunately, Perl, Python, Java, C#, PHP, Javascript, and Visual Basic do check array bounds

Tony Hoare on design principles of ALGOL 60

In his Turing Award lecture in 1980

"The first principle was *security*: ... every subscript was checked at run time against both the upper and the lower declared bounds of the array. Many years later we asked our customers whether they wished an option to switch off these checks in the interests of efficiency. Unanimously, they urged us not to - they knew how frequently subscript errors occur on production runs where failure to detect them could be disastrous.

I note with fear and horror that even in 1980, language designers and users have not learned this lesson. In any respectable branch of engineering, failure to observe such elementary precautions would have long been against the law."

[C.A.R. Hoare, The Emperor's Old Clothes, Communications of the ACM, 1980]

Buffer overflow

- The most common security problem in (machine code compiled from) C and C++
 - ever since the first Morris Worm in 1988
- Check out CVEs mentioning buffer (or buffer%20overflow)
 https://cve.mitre.org/cgi-bin/cvekey.cgi?keyword=buffer
- Ongoing arms race of attacks & defences: attacks are getting cleverer, defeating ever better countermeasures

Other memory corruption problems

Errors with pointers and with dynamic memory (the heap)

- Who here has ever written a C(++) program that uses pointers?
- Who ever had such a program crashing?
- Who has ever written a C(++) program that uses dynamic memory, ie. malloc & free?
- Who ever had such a program crashing?

In C/C++, the programmer is responsible for memory management, and this is very error-prone

- Technical term: C and C++ do not offer memory-safety (see lecture notes on language-based security, §3.1-3.2)

Memory corruption problems

Typical causes

- access outside array bounds
- buggy pointer arithmetic
- dereferencing null pointer
- using a dangling pointer or stale pointer, caused by
 - use-after-free
 - double-free
- forgetting to check for failures in allocation
- forgetting to de-allocate, causing a memory leak
 - not really a memory corruption issue, but rather a memory DoS issue

Spot all (potential) defects

```
1000
1001 void f () {
                                  possible null dereference
       char* buf, buf1;
1002
                                  (if malloc failed)
       buf = malloc(100);
1003
       buf[0] = 'a';
1004
                                   potential use-after-free
                                   if buf & buf1 are aliased
       free (buf1);
2001
       buf[0] = 'b';
2002
                               use-after-free; buf[0] points
                               to de-allocated memory
       free (buf);
3001
                                  memory leak; pointer buf1
       buf[0] = 'c';
3002
                                  to this memory is lost &
       buf1 = malloc(100);
3003
                                  memory is never freed
       buf[0]
3004
                           use-after-free, but now buf[0]
3005 }
                          might point to memory that
                          has now been re-allocated
```

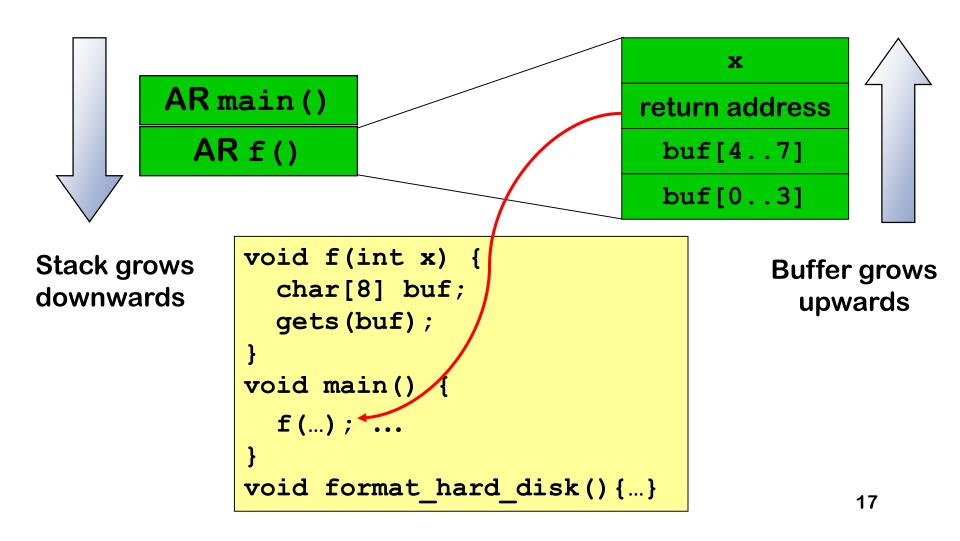

How does classic buffer overflow work? aka smashing the stack

Process memory layout

High **Arguments/ Environment** Stack grows addresses down, by procedure **Stack** calls **Unused Memory** Heap grows **Heap (dynamic data)** up, eg. by malloc .data **Static Data** and new Low Program Code . text addresses

Stack layout

The stack consists of Activation Records:

Stack overflow attack - case 1

What if gets () reads more than 8 bytes?

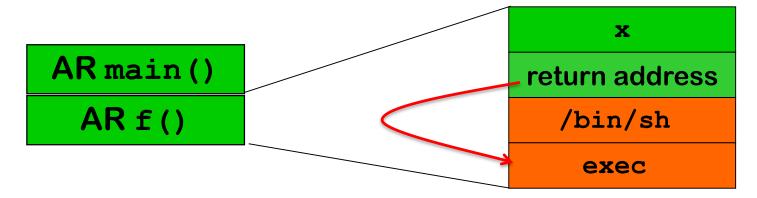

Attacker can jump to abitrary point in the code!

```
X
AR main()
                                 return address
 ARf()
                                  buf [4..7]
                                  buf[0..3]
      void f(int x)
        char[8] buf;
        gets(buf);
      void main()
        f(...); ...
      void format hard disk() {...}
```

Stack overflow attack - case 2

What if gets () reads more than 8 bytes?

Attacker can jump to his own code (aka shell code)

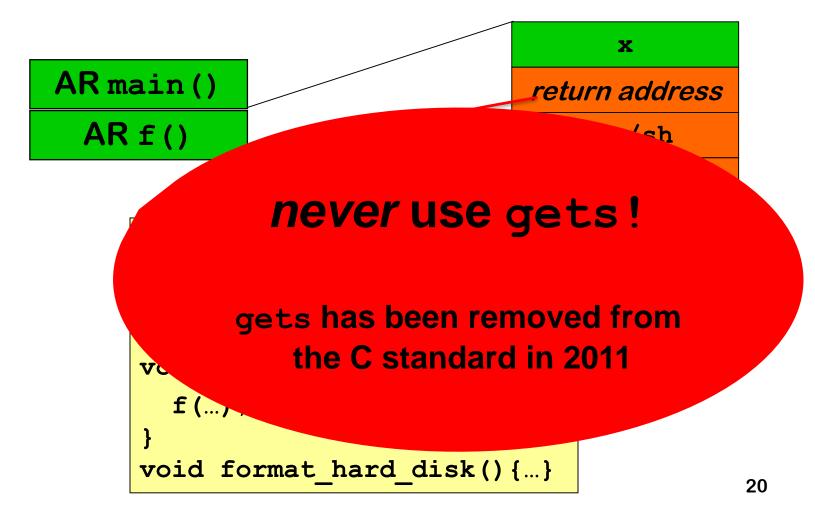

```
void f(int x) {
   char[8] buf;
   gets(buf);
}
void main() {
   f(...); ...
}
void format_hard_disk(){...}
```

Stack overflow attack - case 2

What if gets () reads more than 8 bytes?

Attacker can jump to his own code (aka shell code)

Code injection vs code reuse

The two attack scenarios in these examples

(2) is a code *injection* attack

attacker inserts his own shell code in a buffer and corrupts return addresss to point to this code

In the example, exec('/bin/sh')

This is the classic buffer overflow attack

[Smashing the stack for fun and profit, Aleph One, 1996]

(1) is a code reuse attack

attacker corrupts return address to point to existing code In the example, format_hard_disk

Lots of details to get right!

 knowing precise location of return address and other data on stack, knowing address of code to jump to,

What to attack? More fun on the stack

```
void f(void(*error_handler)(int),...) {
  int diskquota = 200;
  bool is_super_user = false;
  char* filename = "/tmp/scratchpad";
  char[8] username;
  int j = 12;
...
}
```

Suppose the attacker can overflow username

In addition to corrupting the return address, this might corrupt

- pointers, eg filename
- other data on the stack, eg is_super_user, diskquota
- function pointers, eg error_handler

But not j, unless the compiler chooses to allocate variables in a different order, which the compiler is free to do.

What to attack? Fun on the heap

```
struct BankAccount {
  int number;
  char username[20];
  int balance;
}
```

Suppose attacker can overflow username

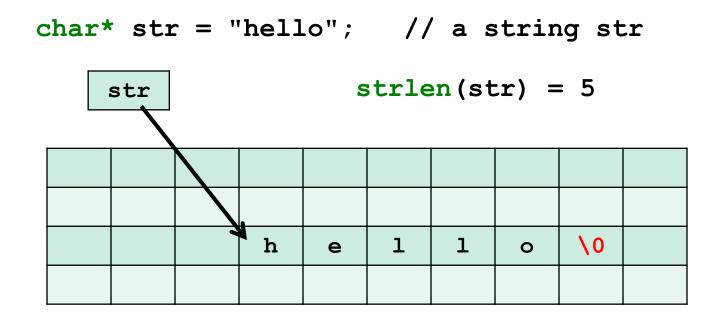

This can corrupt other fields in the struct.

Which field(s) can be corrupted depends on the order of the fields in memory, which the compiler is free to choose.

Spotting the problem

Reminder: C chars & strings

- A char in C is always exactly one byte
- A string is a sequence of chars terminated by a NULL byte
- String variables are pointers of type char*

Example: gets

- Never use gets
 - gets has been removed from the C library
- Use fgets (buf, size, file) instead

Example: strcpy

```
char dest[20];
strcpy(dest, src); // copies string src to dest
```

- strcpy assumes dest is long enough,
 and assumes src is null-terminated
- Use strncpy (dest, src, size) instead

Spot the defect!

```
char buf[20];
char prefix[] = "http://";
char* path;
...
strcpy(buf, prefix);
   // copies the string prefix to buf
strncat(buf, path, sizeof(buf));
   // concatenates path to the string buf
```

Spot the defect! (1)

```
char buf[20];
char prefix[] = "http://";
char* path;
strcpy(buf, prefix);
  // copies the string prefix to buf
strncat(buf, path, sizeof(buf));
  // concatenates path to the string buf
                         strncat's 3rd parameter is number
                        of chars to copy, not the buffer size
                          So this should be sizeof (buf) -7
```

Spot the defect! (2)

```
char src[9];
char dest[9];

char* base_url = "www.ru.nl";
strncpy(src, base_url, 9);
    // copies base_url to src
strcpy(dest, src);
    // copies src to dest
```

Spot the defect! (2)

Spot the defect! (2)

```
char src[9];
                          base url is 10 chars long, incl.
char dest[9];
                         its null terminator, so src will not
                                       be null-terminated
char* base url = "www.ru.nl";
strncpy(src, base url, 9);
   // copies base url to src
strcpy(dest, src);
   //copies src to dest
```

so strcpy will overrun the buffer dest

Example: strcpy and strncpy

Don't replace

```
strcpy(dest, src)
with
   strncpy(dest, src, sizeof(dest))
but with
   strncpy(dest, src, sizeof(dest)-1)
   dst[sizeof(dest)-1] = '\0';
if dest should be null-terminated!
```

NB: a strongly typed programming language would guarantee that strings are always null-terminated, without the programmer having to worry about this...

Spot the defect! (3)

```
char *buf;
int len;
...

buf = malloc(MAX(len,1024)); // allocate buffer
read(fd,buf,len); // read len bytes into buf
```

Spot the defect! (3)

```
char *buf;
int len;
...

buf = malloc(MAX(len,1024)); // allocate buffer
read(fd,buf,len); // read len bytes into buf

What happens if len is negative?
```

The length parameter of read system call is unsigned! So negative len is interpreted as a big positive one!

(At the exam, you're not expected to remember that read treats its 3rd argument as an unsigned int)

Spot the defect! (3)

```
char *buf;
int len;
...

if (len < 0)
    {error ("negative length"); return; }

buf = malloc(MAX(len,1024));

read(fd,buf,len);</pre>
```

A remaining problem may be that buf is not null-terminated; we ignore this for now.

Spot the defect! (3)

Spot the defect! (3)

```
char *buf;
int len;
if (len < 0)
   {error ("negative length"); return; }
buf = malloc(MAX(len, 1024));
if (buf==NULL) { exit(-1);}
             // or something a bit more graceful
read(fd,buf,len);
```

Better still

```
char *buf;
int len;
if (len < 0)
   {error ("negative length"); return; }
buf = calloc(MAX(len, 1024));
      //to initialise allocate memory to 0
if (buf==NULL) { exit(-1);}
             // or something a bit more graceful
read(fd,buf,len);
```

```
#define MAX_BUF 256

void BadCode (char* in)
{     short len;
     char buf[MAX_BUF];

     len = strlen(in);

     if (len < MAX_BUF) strcpy(buf,in);
}</pre>
```

```
#define MAX BUF 256
                              What if in is longer than 32K?
void BadCode (char* in)
{
    short len;
                               len may be a negative number,
    char buf[MAX BUF];
                                   due to integer overflow
    len = strlen(in);
                                           hence: potential
                                            buffer overflow
    if (len < MAX BUF) strcpy(buf,in);</pre>
}
  The integer overflow is the root problem,
```

the (heap) buffer overflow it causes makes it exploitable

See https://cve.mitre.org/cgi-bin/cvekey.cgi?keyword=integer+overflow

And this integer overflow can lead to a (heap) buffer overflow Since 2005 Visual Studio C++ compiler adds check to prevent this

NB absence of language-level security

In a **Safer** programming language than C/C++, the programmer would not have to worry about

- writing past array bounds
 (because you'd get an IndexOutOfBoundsException instead)
- implicit conversions from signed to unsigned integers (because the type system/compiler would forbid this or warn)
- malloc possibly returning null (because you'd get an OutOfMemoryException instead)
- malloc not initialising memory (because language could always ensure default initialisation)
- integer overflow (because you'd get an IntegerOverflowException instead)

• ...

Integer overflow is WAREFINER behaviour! This means

- You cannot assume that overflow produces a negative number;
 so line 2 is not a good check for integer overflow.
- Worse still, if integer overflow occurs, behaviour is undefined, and ANY compilation is ok
 - So compiled code can do anything if start+100 overflows
 - So compiled code can do nothing if start+100 overflows
 - This means the compiler may *remove* line 2 Modern C compilers are clever enough to know x+100 < x is always false, and optimise code accordingly

If tun is a null pointer, then tun->sk is UNDEFINED

What this code does if tun is null is undefined:

ANYTHING may happen then.

So compiler can remove line 5, as the behaviour when tun is NULL is undefined anyway, so this check is 'redundant'.

Standard compilers (gcc, CLang) do this 'optimalisation'!

This is actually code from the Linux kernel, and removing line 5 led to a security vulnerability [CVE-2009-1897]

The CodeRed worm exploited such an mismatch.

Lots of code written under the assumption that characters are one byte contained overflows after switch from ASCII to Unicode

[slide from presentation by Jon Pincus]

```
#include <stdio.h>
int main(int argc, char* argv[])
{    if (argc > 1)
        printf(argv[1]);
    return 0;
}
```

This program is vulnerable to format string attacks, where calling the program with strings containing special characters can result in a buffer overflow attack.

Format string attacks

New type of memory corruption discovered in 2000

- Strings can contain special characters, eg %s in printf("Cannot find file %s", filename);
 Such strings are called format strings
- What happens if we execute the code below? printf("Cannot find file %s");
- What can happen if we execute
 printf(string)
 where string is user-supplied?

Esp. if it contains special characters, eg %s, %x, %n, %hn?

Format string attacks

Suppose attacker can feed malicious input string s to printf(s). This can

read the stack

%x reads and prints bytes from stack, so input

```
%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x
%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x
%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x%x...
```

dumps the stack, including passwords, keys,... stored on the stack

- corrupt the stack
 - %n writes the number of characters printed to the stack, so input 12345678%n writes value 8 to the stack
- read arbitrary memory

a carefully crafted format string of the form

```
\xEF\xCD\xCD\xAB %x%x...%x%s
```

print string at memory address ABCDCDEF

Preventing format string attacks

```
Always replace printf(str)with printf("%s", str)
```

 Compiler or static analysis tool could warn if the number of arguments does not match the format string, eg in

```
printf ("x is %i and y is %i", x);
```

```
Eg gcc has (far too many?) command line options for this:
-Wformat -Wformat-no-literal -Wformat-security ...
```

If the format string is not a compile-time constant, we cannot decide this at compile time, so compiler has to give false positives or false negatives

See https://cve.mitre.org/cgi-bin/cvekey.cgi?keyword=format+string to see how common format strings still are

Recap: buffer overflows

- Buffer overflow is #1 weakness in C and C++ programs
 - because these language are not memory-safe
- Tricky to spot
- Typical cause: programming with arrays, pointers, and strings
 - esp. library functions for null-terminated strings
- Related attacks
 - Format string attack: another way of corrupting stack
 - Integer overflows: often a stepping stone to getting a buffer to overflows
 - but just the integer overflow can already have a security impact; eg think of banking software

Platform-level defences

Platform-level defences

- Defenses the compiler, hardware, OS,... can take, without the programmer having to know
- Some defenses may need OS & hardware support
- Some defenses cause overhead
 - if the overhead is unacceptable in production code, we can still use it when testing
- Some defenses may break binary compatibility
 - eg if a compiler adds extra book-keeping & checks, then all
 libraries may need to be re-compiled with that compiler

Platform-level defenses

- 1. Stack canaries
- 2. Non-executable memory (NX, W⊕X)
- 3. Address space layout randomization (ASLR)

now standard on many platforms

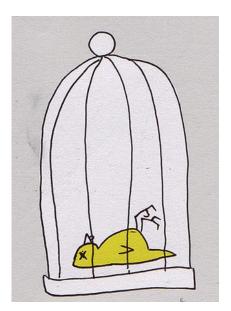

More advanced defenses

- 1. More randomisation: eg. pointer & memory encryption
- 2. More memory safety checks:
 eg. checks on bounds (spatial) or on allocation (temporal)
- 3. Checks on control flow
- 4. Execution-aware memory protection

History shows that all new defenses are eventually defeated...

1. Stack canaries

- A dummy value stack canary or cookie is written on the stack in front of the return address and checked when function returns
- A careless stack overflow will overwrite the canary, which can then be detected
 - first introduced in as StackGuard in gcc
 - only very small runtime overhead

Stack canaries

Stack without canary

Stack with canary

x
return address
buf[4..7]
buf[0..3]

return address

canary value

buf [4..7]

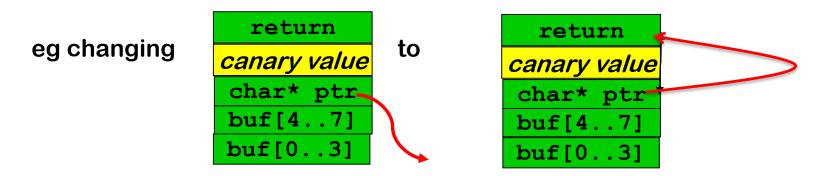

buf [0..3]

Further improvements

- More variation in canary values: eg not a fixed values hardcoded in binary but a random values chosen for each execution
- Better still, XOR the return address into the canary value
- Include a null byte in the canary value, because C string functions cannot write nulls inside strings

A careful attacker can still defeat canaries, by

- overwriting the canary with the correct value
- corrupting a pointer to point to the return address to then change the return address without killing the canary

Further improvements

- Re-order elements on the stack to reduce the potential impact of overruns
 - swapping parameters buf and fp on stack changes whether overrunning buf can corrupt fp
 - which is especially dangerous if fp is a function pointer
 - hence it is safer to allocated array buffers 'above' all other local variables

First introduced by IBM's ProPolice.

- A separate shadow stack
 - with copies of return addresses, used to check for corrupted return addresses
 - Of course, the attacker should not be able to corrupt the shadow stack

Windows 2003 Stack Protection

Nice example of the ways in which things can go wrong...

- Enabled with /GS command line option in Visual Studio
- When canary is corrupted, control is transferred to an exception handler
- Exception handler information is stored ... on the stack!
- Attacker can corrupt the exception handler info on the stack, in the process corrupt the canaries, and then let Stack Protection mechanism transfer control to a malicious exception handler
 - [http://www.securityfocus.com/bid/8522/info]
- Countermeasure: only allow transfer of control to registered exception handlers

2. ASLR (Address Space Layout Randomisation)

- Attacker needs detailed info about memory layout
 - eg to jump to specific piece of code
 - or to corrupt a pointer at known position on the stack
- Attacks become harder if we randomise the memory layout every time we start a program
 - ie. change the offset of the heap, stack, etc, in memory by some random value
- Attackers can still analyse memory layout on their own laptop, but will have to determine the offsets used on the victim's machine to carry out an attack
- NB security by obscurity, despite its bad reputation, is a really great defense mechanism to annoy attackers!
- Once the offset leaks, we're back to square one...

3. Non-eXecutable memory (NX, W⊕X,DEP)

Distinguish

- X: executable memory (for storing code)
- W: writeable, non-executable memory (for storing data) and let processor refuse to execute non-executable code

Attackers can then no longer jump to their own attack code, as any input provide as attack code will be non-executable

Aka DEP (Data Execution Prevention).
Intel calls it eXecute-Disable (XD)
AMD calls it Enhanced Virus Protection

Limitation: this technique does not work for JIT (Just In Time) compilation, where e.g. JavaScript is compiled to machine code at run time.

Defeating NX: return-to-libc attacks

With NX, code *injection* attacks no longer possible, but code *reuse* attacks still are...

- Attackers can no longer corrupt code or insert their own code, but can still corrupt code pointers
- Called control-flow hijack in SoK paper

So instead of jumping to own attack code corrupt return address to jump to existing code esp. library code in libc

```
libc is a rich library that offers lots of functionality, eg.
system(), exec(),
which provides attackers with all they need...
```

re Turnoriented program Ming (ROP)

Next stage in evolution of attacks, as people removed or protected dangerous libc calls such as system()

Instead of using entire library call, attackers can

 look for gadgets, small snippets of code which end with a return, in the existing code base

```
...; ins1 ; ins2 ; ins3 ; ret
```

 chain these gadgets together as subroutines to form a program that does what they want

This turns out to be doable

- Most libraries contain enough gadgets to provide a Turing complete programming language
- ROP compilers can then translate arbitrary code to a string of these gadgets

A newer variant is Jump-Oriented Programming (JOP) which uses a different kind of code fragment as gadgets

More advanced defences

[See SoK Eternal War in Memory paper]

Goals / Building blocks of attacks

Code corruption attack

Overwrite the original program code in memory; impossible with W⊕X

Control-flow hijack attack

Overwrite a code pointer, eg return address, jump address, function pointer, or pointer in vtable of C++ object

Data-only attack

Overwrite some data, eg bool isAdmin;

Information leak

Only reading some data; recall Heartbleed attack on TLS

Control flow hijack via code pointers

- A compiler translates function calls in source code to call <address> or JSR <address> in machine code where <address> is the location of the code for the function.
- For a function call £(...) in C a static address (or offset) of the code for £ may be known at compile time.
 - If compiler can hard-code this in the binary, it is hard for the attacker to mess with, esp. with W⊕X
- For a virtual function call o->m(...) in C++ the address of the code for m typically has to be determined at runtime, by inspecting the virtual function table (vtable).
 - Even with W⊕X attackers may be able to mess with (code pointers in) these tables

Classification of defences [SoK paper]

Probabilistic methods

Basic idea: add randomness to make attacks harder

in location where certain data is located (eg ASLR),
 or in the way data is represented in memory (eg pointer encryption)

Memory Safety

Basic idea: do additional bookkeeping & add runtime checks to prevent some illegal memory access

Control-Flow Hijack Defenses

Basic idea: do additional bookkeeping & add runtime check to prevent strange control flow

More randomness: Pointer Encryption (PointGuard)

- Many buffer overflow attacks involve corrupting pointers, pointers to data or code pointers
- To complicate this: store pointers encrypted in main memory, unencrypted in registers
 - simple & fast encryption scheme: XOR with a fixed value, randomly chosen when a process starts
- Attacker can still corrupt encrypted pointers in memory, but these will not decrypt to predictable values
 - This uses *encryption* to ensure *integrity*.
 Normally NOT a good idea, but here it works.
- Next step: Data Space Randomisation (DSR)
 - encrypt not just pointers, but store all data encrypted in memory

More memory safety

Additional book keeping of meta-data & extra runtime checks to prevent illegal memory access

Different possibilities

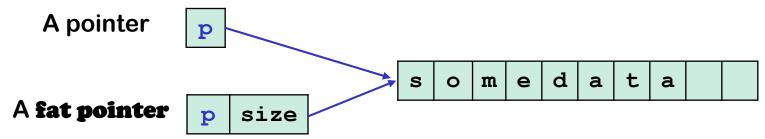

- add information to pointer about size of memory chunks it points to (fat pointers)
- add information to memory chunks about their size (Spatial safety with object bounds)

•

Fat pointers

The compiler

- records size information for all pointers
- adds runtime checks for pointer arithmetic & array indexing

Downsides

- Considerable execution time overhead
- Not binary compatible ie all code needs to be compiled to add this book keeping for all pointers

More memory safety

Additional book keeping of meta-data & extra runtime checks to prevent illegal memory access

Different possibilities

- add information to pointer about size of memory chunks it points to (fat pointers)
- add information to memory chunks about their size (Spatial safety with object bounds)
- keep a shadow administration of this meta-data, separate from the pointers & the existing memory (SoftBounds)
- keep a shadow administration of which memory cells have been allocated (Valgrind, Memcheck, AddressSanitizer or ASan)
 - to also spot temporal bugs, ie. malloc/free bugs

Object-based temporal safety (Valgrind, Memcheck, ASan)

Shadow admin

1	1	1	1	1	1	1	1
0	0	0	0	0	0	0	0
0	0	1	1	1	1	1	1

of allocated memory

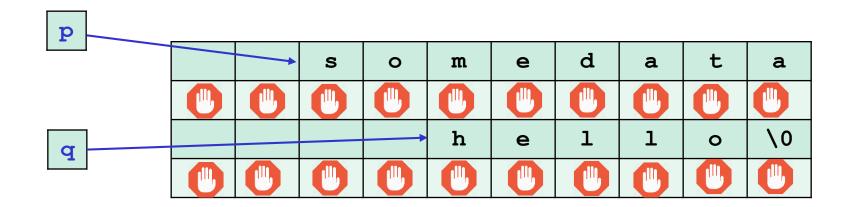

W	0	m	e	d	a	יל	a
0	1	d	j	u	n	k	X
Y	Z	h	е	1	1	0	\0

to keep track of which memory is allocated, to generate runtime error when code tries to read/write unallocated memory

- Can also catch spatial bugs, ie. small buffer overruns, by keeping empty space between allocated chunks (unless overrun is huge)
 - small overrun will end up in this unallocated space
- Cannot spot illegal access via a stale pointer if the data chunk it points to has been re-allocated
 - (eg last bug, line 3004, on slide 14)

Guard pages to improve memory safety

Allocate chunks with the end at a page boundary with a non-readable, non-writeable page between them

Buffer overwrite or overread will cause a memory fault.

Considerable memory overhead

Control Flow Integrity (CFI)

Extra bookkeeping & checks to spot unexpected control flow

Dynamic return integrity

Stack canaries, or shadow stack that keeps copies of all return addresses, providing extra check against corruption of return addresses

Static control flow integrity

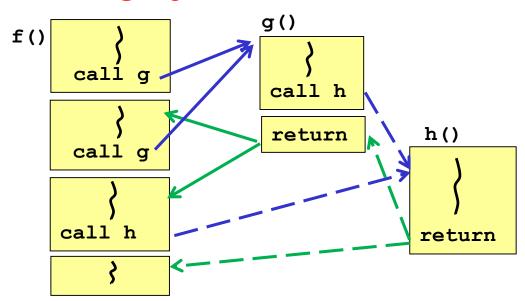

Idea: determine the control flow graph (cfg) and monitor jumps in the control flow to spot deviant behavior

If f() never calls g(), because g() does not even occur in the code of f(), then call from f() to g() is suspect, as is a return from g() to f()

This can detect Return-to-libc and ROP attacks

Static control flow integrity: example code & CFG

```
void f() {
    ...; g();
    ...; h();
    ...
}
void g() { ..h();}
void h() { ...}
```

Before and/or after every control transfer (function call or return) we could check if it is legal – ie. allowed by the cfg

Some weird returns would still be allowed

- eg if we call h() from g(), and the return is to f(), this would be allowed by the static cfg
- Additional dynamic return integrity check can narrow this down to actual call site – using recorded call site on shadow stack

Downsides of static control flow integrity checks

- Requires a whole program analysis
- Use of function pointers in C or virtual functions in C++ (that both result in so-called indirect control transfers) complicate compile-time analysis of the cfg: we'd need
 - a points-to analysis to determine where such code pointers can point to

```
eg in C++, if Animal->eat() can resolve to Cat->eat() or Dog->eat(), so both these addresses are valid targets for transferring control
```

or: simply allow transfer to any function entry point

Exam questions: you should be able to

- Explain how simple buffer overflows work & what root causes are
- Spot a simple buffer overflow, memory-allocation problem, format string attack, or integer overflow in some C code
- Explain how countermeasures such as stack canaries, nonexecutable memory, ASLR, CFI, bounds checkers, pointer encryption, ... - work
- Explain why they might not always work
